

# Overview of Some Key Methods for Observational Studies

Shankar Srinivasan, Ph.D (Presenter), Lihua Yue, PH.D, Lorraine Fang, MS  
and Everton Rowe, Ph.D.

BASS XXVI, Tuesday October 22nd

# Disclosures

- Employment
  - Biostatistician at Celgene Corporation, with salary and stock compensation.
- Blog at [resourcetepee.com](http://resourcetepee.com). Some resources from that blog will be referenced during this tutorial.
- The material presented here represent the views of the presenter and not those of the Celgene Corporation
  - Slides have generic issues and details on Observational Data, some material from his website and a technical report he authored (to be published).

# Outline

- About Observational Data
- General approaches for valid inferences not using Propensity scores
  - Notes on Missing Data, Covariate Adjustment, Exact Methods
- Propensity score based methods with emphasis on the setting with  $> 2$  groups
  - Balancing scores
  - Weights conditional on treatment contrasts
  - IPTW weighting, Matching and Sample size
  - Simulation example
- Questions and Discussion

# Real World Data Issues and Positives

- Missing data requiring imputation methods (see left from Rifkin et al.\*).
- Significant inherent differences between patient cohorts as they are channeled to therapies based on the patient's profile and the patient/physician interaction.
- Without a pre-specified pathway through the data there can be publication bias due to unpublished results and inflation in false positive rates.
- Positives to real world data include
  - very little filtering out of patients though inclusion/exclusion criteria and
  - with retrospective data there are no biases driven by known hypotheses.

# Clinical Trials versus Observational Data

## Clinical Trials

- Usually very controlled in order to reduce noise and detect differences effectively. Project management intensive.
- Specified Interventional Agents
- Limited contexts such as those at diagnosis, maintenance and after relapse.
- Somewhat strict regimen schedules, dosage, and treatment duration.
- Prospectively Collected with near mandatory collection and recording of items in a pre-designed Case Report Form. Very limited missing data.

## Observational Data

- Data includes sources like electronic medical records and registries. Data handling and analysis intensive.
- Typically non-interventional and physician is free to prescribe at will.
- Can record patient experience from diagnosis through progressions and death.
- Regimen schedules, dosage, treatment durations and combinations are highly variable.
- Transcription of available retrospective and prospective data. Missing data at baseline especially “baselines” during the course of disease such as the start of maintenance or post-relapse therapy.

# An Illustrative Example

- We will consider hypothetical real world oncology data with patients receiving an Immune drug or a Chemotherapy. For explanatory ease we will consider relative medians instead of the hazard ratios which are usually reported.
- Physicians channel older patients to Immune drug due to better tolerability. Those receiving the immune drug are on average 10 years older than those receiving the chemotherapy.
- Lets say, that for a 10 year older population, there is a drop in the median survival by 8 months in the aggregate curve.
- An unadjusted analysis might report medians of 60 months and 56 months for the chemo and the immunotherapy groups, whereas the adjusted analysis would have reported median differences of 4 months in the opposite direction of 56 versus 60.
- The adjusted analysis corrects the chemo group down by 4 months and the immune group up by 4 months to account for the 8 month artifact due to age differences.

# Framework for Inferential Analyses With Real World (RW) Data

- Inferential comparisons between cohorts are not valid unless we can argue that all relevant patient characteristics differentiating the groups and possibly effecting outcome have been collected, allowing us to adjust for these differences when comparing cohorts on outcome.
- A fire-wall\* between determining characteristics differentiating groups and the eventual outcome analysis. This and population carve-outs, endpoints, hypotheses and analyses, which are primary, should ideally be pre-specified.
- Start with the screening of factors differentiating cohorts using univariate tests and multivariate variable selection on patient characteristics predicting cohort membership.
- Force in variables predictive of outcome per expert opinion to selected variables.
- Bring in the firewalled outcome data and conduct inferential analyses adjusting for the factors above or analyze differences between culled matched sets.

see Levenson and Yue, [J Biopharm Stat.](#) 2013;23(1):110-21

# Data Imputation in Analyses: Imputation Theory

- Obtains the predictive distribution of the missing data given the remaining patient data.
- Imputes missing data repeatedly using such predictive distributions and creates Multiply Imputed (MI) datasets. Imputes a random smear.
- Inferences from each imputed dataset are combined and reported.
- Analysis under multiple imputation is robust under less restrictive assumptions of Missing at Random (MAR)
- Methods under MAR avoid understating data variability unlike an imputation method which plugs in a specific value instead of a smear.
- 'ANCOVA' like conventional inferential survival analysis in RW setting follows.

# Direct Adjusted Survival Curves using Average Survival Curve Over Covariate Values Over Entire Dataset

## Unstratified - Forced Proportional Hazard and Identical Baseline Hazard

$$\hat{S}_0(t) = \frac{1}{n} \sum_{l=1}^n \exp \{ -\hat{\Lambda}_0(t) e^{\hat{\beta}_2 Z_{2l} + \hat{\beta}_3 Z_{3l}} \}$$

$$\hat{S}_1(t) = \frac{1}{n} \sum_{l=1}^n \exp \{ -\hat{\Lambda}_0(t) e^{\hat{\beta}_1 + \hat{\beta}_2 Z_{2l} + \hat{\beta}_3 Z_{3l}} \}$$

```
proc phreg data=spm;  
  class trt;  
  model spmm*spm_invas(0) = trt diag  
    pinvas ;  
  baseline out=covbase survival =  
    _all_ / diradj group=trt;  
run;
```

## Stratified - Differing Baseline Hazards Across Groups

$$\hat{S}_i(t) = \frac{1}{n} \sum_{l=1}^n \exp \{ -\hat{\Lambda}_{0i}(t) e^{\hat{\beta}_2 Z_{2l} + \hat{\beta}_3 Z_{3l}} \}$$

Here  $i=0$  and  $i=1$  are the strata defined by the treatment variable. Both analyses use averaging of survival curves over for all patients (entire covariate profile set) instead of the the survival curve for average covariate values.

```
proc phreg data=spm;  
  strata trt;  
  model spmm*spm_invas(0) =  
    diag pinvas ;  
  baseline out=stratbase survival =  
    _all_ / diradj ;  
run;
```

# Adjusted Inferential Analysis for those Normal Versus those Abnormal (De-identified) on Reported Measure

Number at Risk:

| Group    | 0 Months | 6 Months | 12 Months | 18 Months | 24 Months | 30 Months | 36 Months | 42 Months | 48 Months | 54 Months | 60 Months | 66 Months | 72 Months | 78 Months | 84 Months | 90 Months |
|----------|----------|----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|
| Abnormal | 76       | 64       | 56        | 46        | 31        | 15        | 5         | 0         |           |           |           |           |           |           |           |           |
| Normal   | 1052     | 969      | 883       | 817       | 486       | 214       | 152       | 25        |           |           |           |           |           |           |           |           |

Covariates: Cohort, Age group, BMI Category, del(17p), Platelet counts

# Exact Matching

| A Disease Related Factor | A Frailty or Co-morbidity Factor | N Control | N Target Therapy | Matched per Group |
|--------------------------|----------------------------------|-----------|------------------|-------------------|
| Level 1                  | Level 1                          | 65        | 32               | 32                |
| Level 2                  | Level 1                          | 21        | 28               | 21                |
| Level 3                  | Level 1                          | 18        | 12               | 12                |
| Level 1                  | Level 2                          | 27        | 22               | 22                |
| Level 2                  | Level 2                          | 29        | 40               | 29                |
| Level 3                  | Level 2                          | 31        | 51               | 31                |
|                          | Totals →                         | 191       | 184              | 147               |

Can be useful when data on all except for a few core factors are unavailable.

Should be the variables most relevant to outcome.

Often erroneously, something perhaps unrelated, such as gender or race is used.

Very easy to communicate to non-statisticians. Leads to loss of data records. Though stratified analyses could be conducted.

# Propensity Score (PS) Methods - More than 2 groups

- For a large number  $p$  of covariates  $\mathbf{X}$ , the results assume that the probabilities of receiving the  $k$  treatments ( $z=1, 2 \dots k$ ) can be determined without bias.
- Consider vector propensity score
  - $\mathbf{e}_s(\mathbf{x})^T = [e_{1s}, e_{2s}, \dots, e_{ks}]$ , with  $e_{is}(\mathbf{x}) = P(z = i | \mathbf{x}, s)$  for a given  $\mathbf{x}$ .
- Proof of the result
  - Let  $\mathbf{e}_s(\mathbf{x})$  equal some vector value  $\mathbf{g}$  and  $\chi_g$  be the set of all covariate values in  $R^p$  such that  $\mathbf{e}_s(\cdot) = \mathbf{g}$ .
  - Then conditional on  $\mathbf{e}_s(\mathbf{x})$  taking a value  $\mathbf{g}$ ,  $\mathbf{x}$  can vary over the set  $\chi_g$  with the probabilities of treatment  $P(z = i | \mathbf{x} \in \chi_g)$  invariantly equal to  $g_i$
  - This makes treatment independent of covariate values conditional on  $\mathbf{e}_s(\mathbf{x})$ .
- Results are extensions of Rosenbaum and Rubin (1983) to  $k > 2$  in Imai and Van Dyke (2004). Outcome differences on balancing are interpretable as a difference in treatment effects with each effect being the aggregate had all subjects in the population received that treatment (ATE).
- We add a limiting conditioning  $\mathbf{s}$  referring to a curated sampling process in observational data to be described in our next slide.

# Curated Sampling in Observational Data

- Observational data sets, not very much unlike those in clinical trials, can often be just as curated though the nature of the curation differs.
- A non-random sampling process characterized by
  - Data acquired depends on availability of records in electronic form, data purchase costs, data quality, availability of certain diagnostic data and time-frames for data pre-processing such as anonymization and IRB approvals for use.
  - Separate observational data collection, prospective or retrospective, conducted to provide one or more quasi-controls to interventional single arm trials requiring similar contexts.
  - Cohort sizes likely unrelated to any past, current or future population proportions of subjects on the therapeutic options studied.
  - The number and identity of therapeutic groups of interest can be influenced by resources available for data agglomeration and the commercial and research interests of the investigators.

# Curated Contrast

- With many therapy options, one investigator may do a data carve-out of subjects on 5 therapy groups and another may pick 3 or 4 which may or may not overlap with the 5.
- Relative group effects of interest may involve further subsets, such as pairwise comparisons of the groups or the comparison of the outcome in one group to that in two others.
- Such relative groups effects are usually assessed using contrasts, in general settings where bias is not expected, usually among randomized groups.
- We refer to contrasts in the observational settings having neither randomization nor random sampling, as curated contrasts.
- The contrasts we use are a string of coefficients, with one for each treatment such that the sum of the contrasts is zero and the sum of the absolute values of the contrasts are equal to 1.0.
  - Example  $[0.5, -0.5, 0]$  and  $[0.5, -0.25, -0.25]$  for three treatment groups.

# Conditioning on the Contrasted Inference as Well

- Consider two vector propensity probabilities (for some two subject given their covariate profiles) of having treatments 1 to 3 of
  1.  $\{0.1, 0.2, 0.7\}$  and  $\{0.2, 0.4, 0.4\}$
  2. Then the contrast  $[0.5, -0.5, 0]$  to compare treatments 1 and 2 ,
  3. would have had balancing propensity scores  $\{0.33, 0.66\}$  for both subjects conditional on the chosen inference if our sampling process did not collect or consider treatment 3.
- Inverse propensity weighting in analysis of outcome, conditionally (# 3 above) requires equal weights while unconditionally (# 1 above) the weights are larger by a factor of 2 for the first subject.
- Rather Odd!

# Curated Contrast Effect (CCE)

- For  $k$  groups, a contrast is defined as
  - a vector  $\mathbf{c}^T = [c_1, c_2, \dots, c_k]$
  - where  $\sum_{i=1}^k c_i = 0$  and  $\sum_{i=1}^k |c_i| = 1$ .
- Let  $C_k$  be the set of all  $\mathbf{c}$  meeting these conditions.
- For propensities  $\{0.1, 0.2, 0.7\}$  and contrast  $[0.5, -0.5, 0]$ , conditionally we get

$$\frac{PS_{ij^*}|c_i|}{\sum_{i=1}^k PS_{ij^*}|c_i|} = \{0.33, 0.66\}$$

- So, absolute value  $|c_i|$  is interpretable as the proportion randomly selected in Group  $i$  independent of the sampling process.
- The probability  $P(z = i | \mathbf{c}) = |c_i|$ .
- We will refer to inferences drawn in this setting as Curated Contrast Effects.

# Unconditional and Conditional Weights

## Unconditional on Contrasted Inference

- Balancing Score

$$\mathbf{e}_s(\mathbf{x})^\top = [e_{1s}, e_{2s}, \dots, e_{ks}], \text{ with}$$

$$e_{is}(\mathbf{x}) = P(z = i | \mathbf{x}, \mathbf{s}) \text{ for a given } \mathbf{x}.$$

- Expression for the Sample Weights

$$\Rightarrow e_{is}(\mathbf{x}) = \frac{P(\mathbf{x} \in \chi_g | z=i, \mathbf{s}) P(z=i | \mathbf{s})}{P(\mathbf{x} \in \chi_g | \mathbf{s})}$$

$$\Rightarrow P(\mathbf{x} \in \chi_g | \mathbf{s}) = \frac{P(\mathbf{x} \in \chi_g | z = i, \mathbf{s}) P(z = i | \mathbf{s})}{e_{is}(\mathbf{x})}$$

- Then the sample weight below will weight a covariate profile in  $\mathbf{x} \in \chi_g$  such that it is not predictive of treatment in the weighted sample.

$$\frac{P(z = i | \mathbf{s})}{e_{is}(\mathbf{x})}$$

## Conditional on Contrast

- Balancing Scores

$$\mathbf{e}_{cs}(\mathbf{x})^\top = [e_{1cs}, e_{2cs}, \dots, e_{kcs}], \text{ with}$$

$$e_{ics}(\mathbf{x}) = P(z = i | \mathbf{x}, \mathbf{c}, \mathbf{s})$$

$$= \frac{P(z = i | \mathbf{x}, \mathbf{s}) * P(z = i | \mathbf{c})}{\sum_{i=1}^k P(z = i | \mathbf{x}, \mathbf{s}) * P(z = i | \mathbf{c})}$$

- Expression for the Sample Weights for covariate profiles to make un-predictive of treatment

$$\frac{P(z=i | \mathbf{c}, \mathbf{s})}{e_{ics}(\mathbf{x})} \text{ for } e_{ics}(\mathbf{x}) \text{ as above}$$

$$P(z = i | \mathbf{c}, \mathbf{s}) = \frac{P(z = i | \mathbf{s}) * |c_i|}{\sum_{i=1}^k P(z = i | \mathbf{s}) * |c_i|}$$

# The Sneetch\* Example

- As you can see, in the world of the Sneetches there is perhaps only one differentiating factor.
- Note that the differentiating factors should plausibly have effect on outcome.
- In addition to a visitation by a dubious entrepreneur selling star-on machines, what is a little less known, is perhaps a less dubious pitch of hair restoration therapies to the Sneetches.
- We will look at balancing scores in this context for 3 treatments for hair growth where there are biases based on the Plain/Star Belly (Covariate).

The sum of weights in a group add up to the group sizes in this context, as is achieved in outcome analysis through the scaling of the inverse PS weights by the average weight in a group.

\*Interactive calculator is available at <https://resourcepeep.com/free-statistical-calculators/observational-data/contrast-effects-in-curated-observational-data/>

# Propensity score ( $p$ ), logit and inverse probability of treatment weighting (IPTW)

- The unconditional weights are consistent with stabilized weights for  $>2$  groups and consistent with the contrast conditional weights only for 2 groups and the contrast  $[0.5, -0.5]$ .
- IPTW: let  $Z_i$  be an indicator variable denoting whether or not the  $i$ th subject was treated; furthermore, let  $p_i$  denote the propensity score for the  $i$ th subject then the inverse probability of treatment weighting  $w_i$  is defined as
  - $w_i = 1/p_i$  for a target therapy subject
  - $w_i = 1/(1-p_i)$  for a control subjects

## Stabilized weights

- $w_i = P(\text{subject in Target})/p_i$  for a Target Therapy subject
- $w_i = P(\text{subject in Control})/(1-p_i)$  for a control subjects

Note:  $P(\text{subject in Target}) = (\text{number of Target subjects}) / (\text{number of Target subjects} + \text{number of Control subjects})$

# The Sneetch\* Example: Simulation\*\* Study

\*Snapshot from goodreads.com

1. Simulate covariate values on a million subjects in the population
2. Generate treatments using coefficients predicting treatment
3. Generate response ( $> 25\%$  reduction), a continuous outcome (% reduction in bald area) and time-to event outcome (time to complete baldness)
4. Pick two curated samples with one selecting 100, 220 and 310 simulated subjects and other selecting after replacement 200, 125 and 75 having treatments 1, 2 and 3 respectively
5. Find conditional (one per contrast) and unconditional weights (one for both contrasts)
6. Use in outcome models and compare estimated treatment effects versus parameters in the simulation of outcome in #3 above.

\*\*The complete derivations of the weighting conditional on the Contrasted inference and the proposed simulation are in a technical report by the author on Research Gate.

# Final Notes on Observational Data

- Data with limitations. Considerable Missing data and Treatment bias issues.
- Improvements may be possible through some standards, which do not increase administrative overload at clinics, or lead to the performance of unneeded procedures.
- In regulatory setting may be useful for rare disease indications, support for accelerated approvals as an add on comparator to single arm interventional trials, and possibly for secondary label approvals.
- Pre-specified pathway through data for analyses to be credible, while specifying sensitivity analyses arounds variants on estimands and methods
- Blinding of analyst to outcome while decisions are being made about analyses
- DONE! Some balding sneetches are waiting!
